Introduction
Abstract

• In this paper we describe a fast and interactive method for simulating and controlling the combustion process together with the decomposition of burning solids.
• The combustion and decomposition processes are integrated to create a physically-based model that runs at interactive rates.
Introduction

• We present a method for simplified modeling and visualization of fire that is easy to implement and works at interactive rates.
• We apply state of the art coarse grid fluid dynamic equation solvers to model the motion of fuel, air, and exhaust gasses in a unified system.
• The heat produced by combustion affects the motion of the air within the computational domain, which in turn affects the shape and motion of the flame.
Introduction

• In addition, this heat transport allows us to simulate self-ignition of objects away from the flame itself.
• The decomposition is defined as a moving boundary problem, modeled using level sets.
• This allows us to easily model the complex, topology changing decomposition process.

Simple Flame Model

3 Gas System
Combustion Process
Heat Transfer
Simple Flame Model

3 Gas System

• In our simple flame model, we transport the fuel and exhaust gases with the motion of the air, creating a dynamic 3-gas system.

• Heat is also transported with the flow of the air, enabling us to model heat distribution inside the computational domain more accurately than any other graphical fire model we know of.
Simple Flame Model

3 Gas System

- To model the air flow, we use a modified version of the Stable Fluids approach.
- We assume there is only one moving gas (air), which is inviscid, incompressible and constant density.
- The fluid motion (air) solution is applied to advect three quantities: fuel gas \( g \), exhaust gas (including smoke) \( a \), and heat \( T \).
Simple Flame Model

3 Gas System

• Since we treat cells as having constant density, we can use heat and temperature interchangeably.
• Some cells (those containing objects to be burned) are marked as filled.
• Finally, a vorticity confinement term is used to compensate for the numerical dissipation in the system.
Simple Flame Model

Combustion Process

• We simulate the combustion process by combining fuel and oxidizer in a cell, creating additional exhaust gas in its place.
• If the heat in the cell is beyond the combustion threshold, we decrease the level of fuel gas, increase the level of exhaust gas, and introduce additional heat into the cell.
Simple Flame Model

Combustion Process

• Note that we define the amount of oxygen in a cell indirectly, by specifying the fuel and exhaust gas in the cell.
• This simplification is not necessarily physically correct, but it enables us to use a single-fluid fuel solver and to model oxygen use and self-extinguishing flames by keeping track of only two gases.
Simple Flame Model

Combustion Process

- Note that although air is not all oxygen, this can be easily accounted for by adjusting the stoichiometric mixture appropriately.
Heat Transfer

- In our system we model heat transfer in three stages:
  - heat transfer in the air,
  - heat transfer between the air and the solid,
  - heat conduction within solids.
- This three-stage heat transfer model enables us to treat solids with varying thermal properties.
- Also, this model is flexible enough that different simulators can be used for any of the three stages, enabling us to work with slower but more accurate simulations of any portion, if desired.
Simple Flame Model

Heat Transfer

• Basic heat convection in air is handled using semi-Lagrangian advection, which simulates moving air currents carrying heat.
• On the other hand, radiative heat transfer is modeled as a diffusion process using implicit integration, enabling us to distribute the heat coming from the combustion process.
• The semi-Lagrangian advection scheme and implicit integration for the diffusion steps follow the same pattern as in the Stable Fluids approach.
Simple Flame Model

Heat Transfer

- Heat transfer between the solid and the air is handled separately.
- For each boundary voxel, we exchange heat to/from the adjacent unfilled “air” voxels.
- We use a simple method for heat exchange, finding the heat differential, and transferring a percentage between them.
- If additional accuracy is required for specific cases, a direct radiant heat term can be incorporated at the expense of interactivity
  - by using a radiosity calculation for the heat coming directly from the visible part of the flame.
Heat Transfer

• Finally, heat transfer inside solids is modeled by simulating diffusion using the heat equation,

\[
\frac{dT}{dt} = k\nabla^2 T
\]

where \( k \) is a constant based on density, thermal conductivity, and specific heat of the material.

• Simulating heat diffusion is relatively simple, and an implicit integrator similar to that for heat diffusion in air (as above) can be used.
Burning Solids and Decomposition

Basic Pyrolysis

Decomposition as a moving boundary

Rigid body simulation
Burning Solids and Decomposition

Basics

• The solids to be burned have two implicit representations, each represented by values along different regular 3D grids.
• Note that these grids do not need to be the same as the grid used to model air motion in the flame simulator.
Burning Solids and Decomposition

Basics

• The first representation is as a signed distance field,
  ▪ which will be used to model decomposition of the object,
  ▪ and the grid resolution depends on how detailed we want our initial/intermediate object boundaries to be.

• The second representation is the amount of solid fuel in the cells,
  ▪ initially based on the percentage of the cell volume occupied by the solid.
Burning Solids and Decomposition

Basics

• These representations can be generated from any initial geometric definition, with a polygonal boundary representation being the most common.
Burning Solids and Decomposition

Basics

• Although the two representations are equivalent at the start of the simulation, we intentionally allow them to diverge during the simulation.
• The solid fuel amount represents how much solid fuel we still have available at the cell.
Burning Solids and Decomposition

Basics

- On the other hand, the distance field represents the decomposed solid including both the solid fuel left and the residue (ashes) in that cell.
- During simulation we consume solid fuel, but leave something behind in form of residue, hence the different behavior of the two representations.
Burning Solids and Decomposition

Pyrolysis

- We define a pyrolysis temperature for every cell in the fuel grid that is filled.
- Recall that pyrolysis is the process by which a solid emits combustible gases.
- Once the cell reaches the pyrolysis temperature a pyrolysis process is applied at every simulation time step.
- This temperature can be set low for volatile solids and arbitrarily high for nonvolatile solids.
Burning Solids and Decomposition

Pyrolysis

- During simulation, when a filled cell enters pyrolysis, fuel gas is released into this cell
  - with velocity in a direction normal to the surface defined by the implicit distance representation.
- The precise amount of fuel released is a function of the temperature of the solid.
- The newly introduced fuel gas will participate in the fluid dynamics solution and flame simulation.
Burning Solids and Decomposition

Decomposition as moving boundary

- The decomposition of the burning solid is modeled as a moving boundary in the distance field representation of the solid.
- The motion of the boundary is defined to take place in the direction of the fuel consumption gradient at a speed based on the rate of solid fuel consumption.

\[ \nu = r_r \nabla \frac{\partial F}{\partial t} \]
Burning Solids and Decomposition

Decomposition as moving boundary

\[ \nu = r_r \nabla \frac{\partial F}{\partial t} \]

- \( \nu \) is the velocity, \( F \) is the solid fuel set, and \( r_r \) is the ratio of burnable vs residue material inside the solid.
- This ratio is used to define how much residue is left in the solid once all the fuel has been used.
Burning Solids and Decomposition

Decomposition as moving boundary

- The distance field implicit representation of the solid can easily handle complex boundaries and topology changes, and also can be easily polygonized for interactive visualization.

- We apply level set methods on the distance field representation to track the moving boundary.
Burning Solids and Decomposition

Decomposition as moving boundary

- The semi-Lagrangian time-stepping scheme defined by Strain works efficiently when adapted to this problem.
- By representing the solids on different grids than the fluid simulator, the decomposition process can execute in its own thread.
We make a significant simplification to the level set simulation,
- by skipping the reinitialization step, without introducing any visual artifacts.

This is possible because our object boundary is always “shrinking” inward instead of moving arbitrarily.

Although the grid values will no longer form an accurate distance field as the simulation progresses, they will still be accurate at the boundary.
Burning Solids and Decomposition

Decomposition as moving boundary

- The two simulations are coupled together
  - by the pyrolysis step (transferring fuel from the solid representation to the fluid representation)
  - and the heat interpolation (transferring heat information from the fluid simulator to the solid representation).
Burning Solids and Decomposition

Decomposition as moving boundary

- A chart showing the interactions between the major stages of the simulations is shown.
Burning Solids and Decomposition

Rigid body simulation

- We implement a simple rigid body simulation by first finding separated pieces.
- This is done by marking grid cells (in the distance field representation) of fixed portions of the solid as “grounded”, then recursively marking cells that border grounded cells as grounded.
- Those not marked as grounded are considered separate.
Rigid body simulation

- Separated pieces are the “active” objects whereas the rest acts as “passive” in the rigid body simulation.
- “Passive” objects are only used for collision and are static in the rigid body simulation, whereas “active” bodies do not participate in the decomposition process, until they stop and become “passive” again.
- This simple paradigm enables us to quickly approximate the effects of gravity on separated pieces in the implicit domain, but does not include internal stresses.
Implementation and Analysis

Implementation
Simplifications
Comparision with other method
And Conclusion
Implementation and Analysis

Implementation

• We have implemented the method presented above and tested it on a number of examples.
• Our simulations are run on an ordinary P4 1.8GHz machine with 512MB of RAM and a 32MB GeForce2 card.
• We are able to simulate a flame interactively (20 fps) for an environment defined on a $20^3$ simulation grid.
Implementation and Analysis

Implementation

- This simulation includes the simulation of air motion, burning and decomposition for one solid, and our simple visualization.
- The grids used to
  - describe the solid are $40^3$ for the distance field representation
  - and $20^3$ for the fuel set representation.
Implementation and Analysis

Implementation

- Our OpenGL based visualization system is intended primarily to demonstrate the simulation methods, and is *not* intended to generate production-quality images.
- This visualization is limiting, but it is useful for understanding the simulation effects at interactive rates.
Implementation and Analysis

Simplifications

• Our methods make a number of simplifying assumptions, which lead to some shortcomings.
• We describe below some of our key assumptions, simplifications, and shortcomings, along with the reason we accept them.
Simplifications

• Single fluid model.
  ▪ Although air, fuel gas, and exhaust gases will have different properties, we choose to model the system with a single fluid.
  ▪ We therefore do not capture properties such as the mixing of fluids of different viscosity.
  ▪ However, our model still captures the dominant large-scale motion of heated air.
Simplifications

• Constant density air.
  ▪ Our assumption that the sum of the air, fuel, and exhaust gas in a cell is constant is somewhat unrealistic, and the effects of combustion are not directly modeled.
  ▪ However, accurately simulating effects such as changes in pressure or gas compression would likely cause the simulation to become far too slow.
Implementation and Analysis

Simplifications

• Decoupled heat transfer.
  - Separating heat transfer into three stages, rather than using a unified simulation is somewhat inaccurate.
  - However, the inaccuracies do not appear significant, and the decoupling allows us to use different solvers of varying accuracy.
Implementation and Analysis

Simplifications

• Simulating heat in fluid domain.
  ▪ By simulating heat transfer in only the fluid domain, heat can diffuse farther into a solid than would be possible if heat were modeled in the representation of the object itself.
Implementation and Analysis

Simplifications

- Simplified decomposition model.
  - The actual physical decomposition process of burning objects is quite complicated and would involve detailed modeling of the solid structure at a very low level, however it is impractical to attempt to model such a process in an interactive system.
Simplifications

• Simplified solid simulation.
  - We have only modeled simple rigid body motions, and have not modeled internal stresses and strains on the objects.
Implementation and Analysis

Comparison with other methods

- The two primary distinctions between our method and other recent methods are
  - (a) that it runs at interactive rates,
  - and (b) that it simulates the entire burning process.
- The work of Nguyen et al.[6] achieves probably the best physical-simulation-based results.
- Their method captures the flame shape, including fine-scale details, by simulating the interface between two fluids.
Implementation and Analysis

Comparison with other methods

• However, it does not model combustion, and does not address issues such as heat transport through the entire simulation domain.

• In our simulation, on the other hand, heat, generated by a simple model of the combustion reaction, is one of the main driving forces.
Implementation and Analysis

Comparison with other methods

• They inject fuel from the solid into the fluid simulation system, however, they make no attempt to simulate any of the other effects within the solid - fuel consumption, object decomposition and heat distribution within the solid.

• Finally, their simulation and rendering times, though producing more detailed results, are orders of magnitude longer than ours.
Conclusion

- Our system integrates the fire and combustion process together with the ignition, burning and decomposition of solids.
- Although we have made a number of simplifying assumptions, our system is capable of modeling basic flame and decomposition behavior.
- This occurs at interactive frame rates on standard PC hardware.
- The simulation model we have presented is flexible, allowing for easy replacement of simulators in any one part of the model, fairly independently of the other portions of the model.
Conclusion

• There are several avenues open for future work.
  ▪ For example, if we sacrifice interactivity, we can have more detailed models for both flame simulation and solid decomposition.
  ▪ In particular, we believe an interactive simulation of extended rigid body motions and limited internal stress calculations will be a challenging task.
